ABSTRACT

Background and Objective: Models of the cardiomyocyte action potential have contributed immensely to the understanding of heart function, pathophysiology, and the origin of heart rhythm disturbances. However, action potential models are highly nonlinear, making them difficult to parameterise and limiting to describing 'average cell' dynamics, when cell-specific models would be ideal to uncover inter-cell variability but are too experimentally challenging to be achieved. Here, we focus on automatically designing experimental protocols that allow us to better identify cell-specific maximum conductance values for each major current type.

Methods and Results: We developed an approach that applies optimal experimental designs to patch-clamp experiments, including both voltage-clamp and current-clamp experiments. We assessed the models calibrated to these new optimal designs by comparing them to the models calibrated to some of the commonly used designs in the literature. We showed that optimal designs are not only overall shorter in duration but also able to perform better than many of the existing experiment designs in terms of identifying model parameters and hence model predictive power.

Conclusions: For cardiac cellular electrophysiology, this approach will allow researchers to define their hypothesis of the dynamics of the system and automatically design experimental protocols that will result in theoretically optimal designs.

1. Introduction

Cardiac cellular electrophysiology is the study of how cells manipulate ionic concentrations and membrane voltage to initiate and synchronise heartbeats. Having demonstrated their usefulness in fundamental research, quantitative models of the action potential (AP) are increasingly being used [1] in safety-critical applications [2,3] such as optimising patient treatments [4,5] or assessing drug safety [6]. These models contain several parameters, which may represent chemical properties such as binding rates, but also patient and even cell-specific properties such as ion current conductances (which are determined by gene expression levels). In many cases such parameters are not measured directly, but *inferred* in-

directly from experimental recordings of membrane potential or transmembrane current. To create accurate models, we need to ensure the experiments used in their creation contain sufficient information on all parameters we need to infer. However, the experiments used in this process have not usually been designed with model calibration in mind, and as a result some parameters may be poorly constrained by the available data [7,8]. Optimal experimental design (OED) is a method of designing experiments which uses an objective approach to elicit data containing "optimal information" for model calibration [9–12]. It is extremely popular in physical sciences such as geosciences [13,14], mechanical engineering [15,16], chemical engineering [17,18], etc. In this study, we apply the techniques of OED to cardiac cellular electrophysiology to expedite the development of AP models suitable for both basic research and safety-critical applications.

The electrophysiological properties of many types of isolated cells can be studied and examined via patch-clamp experiments [19] in which the experimenter either controls ('clamps') the cell's

membrane potential and measures the resulting transmembrane current (voltage-clamp mode), or controls the current while measuring potential (current-clamp mode). In either mode, a pre-determined waveform (i.e. a sequence of voltages or currents) is applied, which we shall refer to as the experimental *protocol*. OED is a methodology of designing protocols based on the intuition that a model parameter can only be estimated from a measured model output (e.g. a current or voltage trace) if that output is strongly sensitive to the parameter value during the experiment. In short, it produces protocols that *maximise* (in some exact sense to be chosen by the experimenter) the model output's sensitivity to all parameters of interest.

We apply an OED strategy to design experimental protocols that allow us to better identify cell-specific maximum conductance values for the major current types in mathematical cardiac myocyte models. Using simulation results from a controllable, understandable cellular system, we show that OED can successfully be applied to both voltage-clamp and current-clamp experiments to obtain cell-specific models. Moreover, the results demonstrate how OED protocols perform better than many of the existing experiments in the literature, in terms of reducing uncertainty in model parameters and its theoretical predictive power. This study provides a road map for researchers in cardiac cellular electrophysiology to automatically design theoretically-optimal experimental protocols.

2. Methods

In the design of experiments, the results of OED are experimental designs that are optimal with respect to some statistical criteria—*optimal design measures*. Formally, we consider a (controlled) nonlinear differential equation model of the form

$$\frac{d\mathbf{x}}{dt} = \mathbf{f}(\mathbf{x}, \mathbf{u}(\mathbf{d}), \boldsymbol{\theta}), \quad (1)$$

$$\mathbf{y} = \mathbf{h}(\mathbf{x}, \mathbf{u}(\mathbf{d}), \boldsymbol{\theta}), \quad (2)$$

where \mathbf{x} is the vector of model states, \mathbf{u} is the vector of system inputs, $\boldsymbol{\theta}$ is the vector of model parameters. \mathbf{f} and \mathbf{h} are the systems of equations, where \mathbf{f} describes the dynamical equations, and \mathbf{h} maps the solutions of the dynamical equations to the vector of observables \mathbf{y} , i.e. the model outputs that we compare with data. We assume that the system input \mathbf{u} can be parameterised with \mathbf{d} , i.e.

\mathbf{d} is the vector of parameters that controls the experimental conditions. For example, if \mathbf{u} is an applied voltage-clamp protocol, \mathbf{d} could be the voltages and durations of its steps; if \mathbf{u} is an applied current stimulus, \mathbf{d} could be the durations between each stimulus, as described in details in the next sections. The optimisation of the experimental design procedure is then defined as

$$\hat{\mathbf{d}} = \operatorname{argmin}_{\mathbf{d}} \Phi(\mathbf{d}), \quad (3)$$

where the function Φ represents the optimal design measure to be minimised.

All optimal design measures discussed in this paper assume the model calibration process to be least-square estimation, maximum likelihood estimation, or posterior estimation; if one considers a different calibration process, such as bounded-error parameter estimation (also known as guaranteed parameter estimation) or approximate Bayesian computation (ABC), biases may be introduced, and a different set of design measures should be used [17]. All methods are implicitly conditional on the chosen set of model equations, i.e. they are only optimal for the models used during the design; this is a general limitation of model-based OED.

2.1. Action potential models for OED

We consider cardiac cellular electrophysiology models of APs under either a voltage-clamp or a current-clamp experiment, and we aim to optimise either the voltage-clamp or the current-clamp protocol for conductance identification. In practise, we design experiments and perform the fitting to data with a proposed model which would be our current best representation of reality. A schematic overview of the method is given in Fig. 1.

Designing experiments with a single model

Here, we first use a widely-used adult ventricular (epicardial) AP model by O'Hara et al. [20] as a 'proposed model'. Under the voltage-clamp configuration, the observed current I_{obs} can be expressed as

$$I_{\text{obs}}(t) = \sum_j g_j \cdot x_j(V_m, t), \quad (4)$$

where g_j is the maximum conductance or permeability and $x_j(V)$ is some nonlinear function of the voltage V_m for the current of type

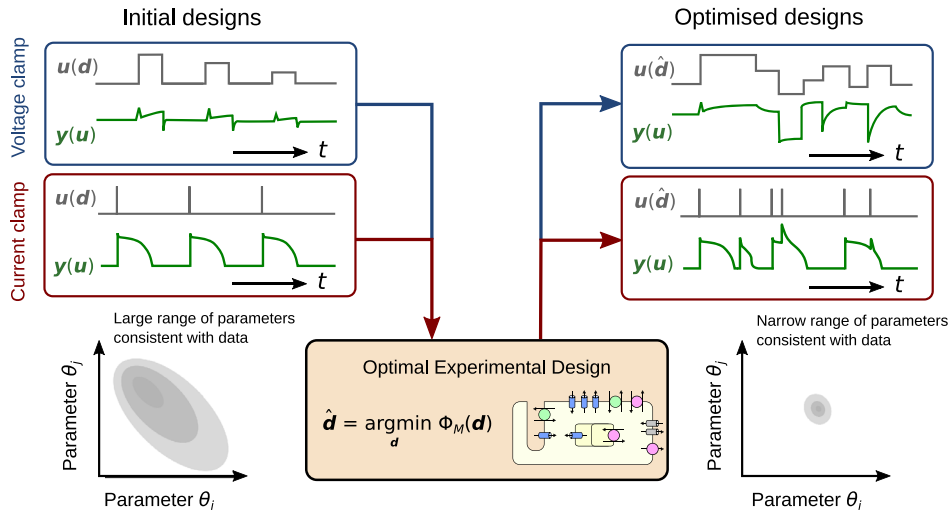

Fig. 1. A schematic of optimal experimental design for patch-clamp experiments. Initial designs (left, $\mathbf{u}(\mathbf{d})$) of the voltage-clamp and current-clamp experiments, which can commonly be found in the literature or perhaps are 'intuitive' choices of the design inputs (\mathbf{d}), elicit uninformative data/observables $\mathbf{y}(\mathbf{u})$ for calibrating complex mathematical models, leading to a wide posterior for the model parameters $\boldsymbol{\theta}$ (shown for two parameters but the principle applies for higher numbers of parameters). Optimal experimental designs with the mathematical model M under a certain statistical criterion Φ_M derive optimised designs (right, $\mathbf{u}(\hat{\mathbf{d}})$) with non-intuitive choices of design inputs $\hat{\mathbf{d}}$ which elicit informative data for calibration, and lead to narrower parameter posteriors.

j , and we consider the major currents only (Eq. (6)). These non-linear functions $x_j(V)$ are the product of the ‘kinetics’ (describing the voltage-dependent opening and closing of ion channels in response to changes in membrane voltage) and the ‘driving term’ of the currents, either the Ohmic (membrane potential minus reversal potential) term or the Goldman-Hodgkin-Katz flux equation.

For our voltage-clamp experimental designs, the output of interest (\mathbf{y} in Eq. (2)) is the observed current I_{obs} , and the vector of system inputs \mathbf{u} describes the applied voltage-clamp protocol $V_m(t)$.

Alternatively, for current-clamp experiments, the observed membrane voltage V_m follows

$$\frac{dV_m}{dt} = -\frac{1}{C_m}(I_{\text{obs}}(t) + I_{\text{stim}}(t)), \quad (5)$$

where $I_{\text{obs}}(t)$ is the same as Eq. (4). In this case, the membrane voltage V_m is the output of interest (\mathbf{y} in Eq. (2)), and the vector of system inputs \mathbf{u} describes the externally-applied current-clamp protocol, i.e. the stimulus current $I_{\text{stim}}(t)$.

We assume that the x_j kinetics equations and their parameters are known (and correct). We are interested in finding all g_j , which determine the magnitude of the currents when the channels are fully open, therefore we have

$$\boldsymbol{\theta} = \{g_{\text{Na}}, g_{\text{CaL}}, g_{\text{Kr}}, g_{\text{Ks}}, g_{\text{to}}, g_{\text{NaCa}}, g_{\text{K1}}, g_{\text{NaK}}\} \quad (6)$$

to be inferred, which are the maximum conductance or permeability of the fast sodium current, the L-type calcium current, the rapid-delayed rectifier potassium current, the slow-delayed rectifier potassium current, the transient potassium current, the sodium-calcium exchanger current, the inward rectifier potassium current, and the sodium-potassium pump current, respectively. We note that this ignores some smaller background currents in the model.

Simulations were run using Myokit [21], with tolerance settings for the CVODE solver [22] set to $\text{abs_tol} = 10^{-8}$ and $\text{rel_tol} = 10^{-10}$.

Designing experiments with an averaged measure over models

Each OED is optimal for the model used to perform the design. However, we may want to obtain a design that is optimal for a range of biological assumptions instead of focusing on one particular model, so that the same data can be used to study multiple similar models. Therefore, we also consider using multiple models for calculating the cost function; instead of using only one model to optimise the experiment while the true data generating process could potentially be more similar to another model. That is, if we have N_M proposed models, then each model output $I_{\text{obs},M}$ (for voltage clamp) or $V_{m,M}$ (for current clamp) is used to calculate an optimal design measure Φ_M , and we optimise the experimental protocol parameters using

$$\hat{\mathbf{d}} = \underset{\mathbf{d}}{\text{argmin}} \mathbb{E}_M(\Phi_M(\mathbf{d})). \quad (7)$$

It minimises the mean of the measures Φ_M calculated independently for each of the N_M proposed models. Here we use five adult ventricular (epicardial) AP models to represent an averaged behaviour: O'Hara et al. [20], ten Tusscher et al. [23], Fink et al. [24], Chang et al. [25], and Tomek et al. [26]. Note that the averaged measure (over models) is used only for the designing the experiments, i.e. obtaining $\hat{\mathbf{d}}$, and only one model will be used at a time during predictions.

2.2. Experiments to be optimised: Two modes of experiments

We design the experiments by varying the system input $\mathbf{u}(\mathbf{d})$. As described in the model section, we could measure the system with two modes: voltage clamp and current clamp.

Parameterising voltage-clamp experiment designs

The voltage-clamp protocol V is the system input $\mathbf{u}(\mathbf{d})$, and we choose it to be a piecewise function defined as

$$\mathbf{u}(\mathbf{d}) = V(t) = \begin{cases} V_1, & 0 \leq t < T_1 \\ V_2, & T_1 \leq t < T_2 \\ \vdots & \vdots \\ V_N, & T_{N-1} \leq t < T_N. \end{cases} \quad (8)$$

The vector of parameters that defines the voltage-clamp protocol is

$$\mathbf{d} = \{V_1, T_1, V_2, T_2, \dots, V_N, T_N\} \quad (9)$$

for a N -step protocol; equivalently we can define $\Delta T_i = T_i - T_{i-1}$ with $T_0 = 0$, then we obtain

$$\mathbf{d} = \{V_1, \Delta T_1, V_2, \Delta T_2, \dots, V_N, \Delta T_N\}. \quad (10)$$

In order to ensure the resulting voltage-clamp protocol V is feasible to be run experimentally, we constrain the protocol to have $V_i \in [-120, 60]$ mV and $\Delta T_i \in [50, 2000]$ ms for all i , which defines the protocol parameter space. We choose N to be 20, giving a maximum protocol duration of 40s. We applied both the local sensitivity analysis (LSA) and global sensitivity analysis (GSA) designs for this experimental setting.

In theory, the voltage-clamp protocol can be replaced with any arbitrary function, e.g. a sum of sinusoidal functions [27], as long as it can be parameterised with some vector of parameters \mathbf{d} . However, the benefit of choosing such a piecewise step function is that it can be directly applied in any patch-clamp system, including some of the high-throughput automated patch-clamp systems such as the SyncroPatch from Nanion Technologies [28,29].

Parameterising current-clamp experiment designs

In the current-clamp mode, the stimulus current I_{stim} is the system input $\mathbf{u}(\mathbf{d})$. Partly inspired by Groenendaal et al. [30], who randomly applied stimulus pulses to create an informative non-uniform protocol, here we optimise when to apply stimulus pulses. We parameterised the current-clamp protocol as follows: the stimulus current with an amplitude \bar{I}_{stim} and duration T_{stim} is applied at times T_1, T_2, \dots, T_N (and is otherwise zero), where $T_{i+1} > iT_{\text{stim}} + T_i$. The values of \bar{I}_{stim} and T_{stim} are chosen to be those given in the original publication of each model. Similar to the voltage-clamp protocol parameterisation, equivalently we can define $\Delta T_i = T_{i+1} - iT_{\text{stim}} - T_i$, giving

$$\mathbf{d} = \{\Delta T_1, \Delta T_2, \dots, \Delta T_N\}. \quad (11)$$

We further constrain $\Delta T_i \in [100, 2000]$ ms, $\forall i$, to make the designed experiments practically usable. We applied only the LSA designs for this experimental setting; to apply GSA designs for current-clamp experiments, we would need to first explore the boundaries (not necessarily being a hypercube) of the parameter space that generate APs.

2.3. OED design measures

Local sensitivity analysis (LSA)-based designs

The sensitivity matrix based on LSA, $\mathbf{S}_L(\mathbf{d} | \boldsymbol{\theta} = \hat{\boldsymbol{\theta}})$, is defined as

$$(\mathbf{S}_L)_{ij} = \left. \frac{\partial y_i}{\partial \theta_j} \right|_{\boldsymbol{\theta} = \hat{\boldsymbol{\theta}}}. \quad (12)$$

Here the subscript i (row) in y_i runs through all model outputs in \mathbf{y} and all sampled time points t_k^1 , and the subscript j (column) θ_j

¹ That is, for N_o model outputs and N_t time points, $i = 1, 2, \dots, N_o, N_o + 1, N_o + 2, \dots, N_o \times N_t$.

goes over all model parameters in θ . The Fisher information matrix (FIM) is given by

$$\text{FIM}(\theta) = \mathbf{S}_L^T \Sigma^{-1} \mathbf{S}_L, \quad (13)$$

where Σ is the covariance matrix of the measurement data (noise). Here we assume that data are from a single output (a single observed time series trace) with independent and identically distributed (i.i.d.) zero mean and σ^2 variance Gaussian noise through time such that $\Sigma = \sigma^2 \mathbf{I}$ with σ constant and \mathbf{I} the identity matrix.

Many local design criteria are based on the parameter (co)variance matrix defined as

$$\mathbf{C}_\theta = \mathbb{E}[(\theta - \mathbb{E}[\theta])(\theta - \mathbb{E}[\theta])^T] \geq \text{FIM}(\theta)^{-1}, \quad (14)$$

where $\mathbb{E}[\cdot]$ denotes the expected value. This describes the covariance of the estimates of a fixed true parameter set². For any unbiased estimator, where the expected value is equal to the true value of the parameter set, a lower bound for the variance is given by the inverse of the FIM (the inequality in Eq. (14)), known as the Cramér-Rao bound [31]. Therefore, to evaluate the local design criteria based on the covariance matrix, we use the Cramér-Rao bound and calculate $\text{FIM}(\theta)^{-1}$ instead [18,31]. In fact, equality with the Cramér-Rao bound would be achieved as K (number of observations) approaches infinity

$$\lim_{K \rightarrow \infty} \mathbf{C}_\theta = \text{FIM}(\theta)^{-1}. \quad (15)$$

For proof of Eq. (15) see, for example, Pant [32]. Note, \mathbf{C}_θ , FIM, and \mathbf{S}_L all depend on the choice of the system input \mathbf{d} .

Common criteria for local design are the ‘alphabetic family’ [10,31]. These criteria each represent a cost function to be minimised, a subset of them [A-optimal, D-optimal, and E*-optimal designs, 33] are given in Table 1, where $\lambda_{\max}(\mathbf{X})$ and $\lambda_{\min}(\mathbf{X})$, respectively, denote the maximum and minimum eigenvalues of a matrix \mathbf{X} .

The design criteria in Table 1 are parameter based criteria [33]: these cost functions (as functions of the FIM) can be interpreted as properties (the shape and size) of the confidence hyper-ellipsoid (a generalisation of the confidence interval for multivariate statistics) for the parameters θ [34,35]. Therefore, by improving certain properties of the confidence ellipsoid, the uncertainty of the inferred parameters using the data measured under an optimally designed protocols should (in theory) be reduced.

One obvious limitation of the local designs is that they are local, i.e. they depend on a particular choice of the model parameters ($\theta = \hat{\theta}$ in the equations above). Hence the design is only guaranteed to be optimal for that particular choice of parameters. However, we do not know the true model parameters in the experiments by definition. This issue could be alleviated by replacing the local sensitivity with an averaged sensitivity matrix

$$\mathbb{E}[(\mathbf{S}_L)_{ij}] = \int_{\Theta} (\mathbf{S}_L)_{ij} p(\theta_j) d\theta_j, \quad (16)$$

where $p(\theta_j)$ is the probability density function of the j^{th} parameter, defined over a domain Θ (a subspace of the parameter space). The integral in Eq. (16) can be approximated using Monte Carlo simulations. Although this averaged sensitivity matrix has been shown to give a more robust design [36], it does not take the multivariate interaction into account [18], and hence the framework of global sensitivity comes into play.

Global sensitivity analysis (GSA)-based designs

One of the most straight forward ways of doing GSA-based design is by replacing the \mathbf{S}_L in Table 1 with a sensitivity matrix based on GSA methods [18,37,38]. We can use variance-based

² Note that under this framework, the true parameters do not vary, as opposed to the Bayesian framework where the true parameters can be treated as random variables.

Table 1

Local design criteria for OED. Here we have assumed the parameter covariance matrix \mathbf{C}_θ for some given model parameters θ can be approximated as $\sigma^{-2}[\mathbf{S}_L^T \mathbf{S}_L]^{-1}$, where σ^{-2} is dropped from the design criteria (cost functions) as it is assumed to be constant. E* is the modified E criterion.

Local design criteria	Cost functions
A-optimal design	$\Phi_A = \text{trace}([\mathbf{S}_L^T \mathbf{S}_L]^{-1})$
D-optimal design	$\Phi_D = \det([\mathbf{S}_L^T \mathbf{S}_L]^{-1})$
E*-optimal design	$\Phi_{E^*} = \lambda_{\max}([\mathbf{S}_L^T \mathbf{S}_L]^{-1}) / \lambda_{\min}([\mathbf{S}_L^T \mathbf{S}_L]^{-1})$

Table 2

Global design criteria for OED based on a generalisation of the local design criteria in Table 1 using a GSA method.

GSA-based design criteria	Cost functions
A-optimal design	$\Phi_A^{\text{GSA}} = \text{trace}([\mathbf{S}_G^T \mathbf{S}_G]^{-1})$
D-optimal design	$\Phi_D^{\text{GSA}} = \det([\mathbf{S}_G^T \mathbf{S}_G]^{-1})$
E*-optimal design	$\Phi_{E^*}^{\text{GSA}} = \lambda_{\max}([\mathbf{S}_G^T \mathbf{S}_G]^{-1}) / \lambda_{\min}([\mathbf{S}_G^T \mathbf{S}_G]^{-1})$

methods such as the Sobol method [also known as the Sobol indices, 39]. The Sobol method decomposes the variance of the model output into fractions, and attributes these variances to parameters or sets of parameters, usually referred to as the order. The first-order Sobol index attributes these variances to each parameter θ_j alone; whilst higher order Sobol indices attribute the variances to different combinations of parameters. These variances are calculated using a set of parameters sampled within a domain Θ , a subspace of the parameter space. These parameters can be sampled using various methods, for example Monte Carlo methods, or some low-discrepancy sequences (including Sobol sequences or Latin hypercube sampling); we used the extension of the Sobol sequence by Saltelli [40] and Saltelli et al. [41] here. The first-order Sobol sensitivity index is given by

$$(\mathbf{S}_G)_{ij} = \frac{1}{\text{Var}(y_i)} \text{Var}_{\theta_j}(\mathbb{E}_{\theta_{-j}}[y_i | \theta_j]), \quad (17)$$

where $\text{Var}(y_i)$ is the total variance of the model output y_i , $\text{Var}_{\theta_j}(X) = \mathbb{E}_{\theta_j}(X^2) - (\mathbb{E}_{\theta_j}(X))^2$ denotes the conditional variance only over parameter θ_j , and $\mathbb{E}_{\theta_{-j}}[\cdot]$ indicates the expected value taken over all parameters θ except parameter θ_j . Criteria using \mathbf{S}_G are given in Table 2. Note that one may further include higher-order Sobol indices for analysing multivariate parameter interactions and dependencies [38], but since we would like to maximise the independent sensitivity of the parameters for the experimental design, using the first-order sensitivities is sufficient.

2.4. Optimisation of protocol designs

To perform the optimisation of the protocols as defined by Eq. (3), we optimise the design measures (cost functions) by varying the protocol parameters (\mathbf{d} in Eq. (10) for voltage clamp and in Eq. (11) for current clamp). The protocol was initialised with parameters $\mathbf{d} = \mathbf{d}_0$ randomly sampled uniformly within the boundaries (the protocol parameter space) defined in Section 2.2. Optimisations were performed using the covariance matrix adaptation evolution strategy [42] via our open source Python package, PINTS [43]. This was repeated 10 times with different initial protocol parameters, and the best result out of all repeats was used and presented in the results.

To compute the Sobol indices, we define a hypercube for the model parameter space Θ , where each conductance value g_j in Eq. (6) can be scaled from $e^{-2} \approx 0.14$ to $e^2 \approx 7.39$ times its original value. We use the Saltelli et al. [41] extension of a Sobol sequence to generate 512 parameter samples within this parameter space Θ for computing the Sobol indices.

To numerically calculate the local sensitivity matrix \mathbf{S}_l , we use the first-order central difference to approximate the local derivatives with a step-size of 0.1% of the parameter values. It may be worth noting that although LSA-based criteria require local derivatives, we are not truly interested in (local) infinitesimal changes when designing the protocols, hence a reasonable approximation of the derivatives typically suffices.

2.5. Comparing the performance of OEDs

Cross-measure evaluations

We defined a cross-measure matrix \mathbf{X} for each optimised protocol, such that each entry $X_{i,j}$ was the criterion j score for this protocol with currents generated by model i , with $1 < j < N_{\text{measure}}$ and $1 < i < N_{\text{model}}$. The models indexed by i were the ten Tusscher et al. [23] model, the Fink et al. [24] model, the O'Hara et al. [20] model, the Chang et al. [25] model, the Tomek et al. [26] model, and the averaged model. The criteria indexed by j were the LSA A-, D-, E*-designs, and the GSA A-, D-, E*-designs, respectively, for the voltage-clamp mode; j were the LSA A-, D-, E*-designs, respectively, for the current-clamp mode.

The numerical values for different cost functions were not directly comparable, so we normalised the values. Normalisation should be better than using a simple ranking as it should highlight outliers better. Outliers concerned us here, because we expected the best protocols to be robust to the model (possible current kinetics in reality) and to perform well under all measures. Ideally, we would like to have a protocol that is good under all criteria and all possible models of kinetics. The normalisation for each entry was calculated using $\bar{X}_{i,j} = (X_{i,j} - a_{i,j}) / (b_{i,j} - a_{i,j}) \times 100\%$, where $a_{i,j}$ and $b_{i,j}$ were the minimum (best) and maximum (worst) scores seen across all the protocols (including both voltage-clamp and current-clamp experiments). Note the normalisation (percentile) was calculated with only the optimised protocols, i.e. without the benchmark protocols, for clarity. Therefore the percentiles shown in Figs. 6 and 7 were not necessarily within 0 to 100%. at the entry i, j (i.e. with this criterion and current model).

Practical evaluations

We further evaluated the optimised protocols from a practical point of view. We generated synthetic data under these protocols with synthetic noise, and we assessed identifiability of the parameters in Eq. (6).

We generated synthetic data using the O'Hara et al. [20] model with $\sim \mathcal{N}(0, \sigma^2)$ as the synthetic noise, where $\sigma = 0.15 \text{ AF}^{-1}$ for voltage clamp and $\sigma = 0.15 \text{ mV}$ for current clamp. Then the same model was used to fit the synthetic data, to test the ideal case where we know the ground truth kinetics. We reparameterised the models with a scaling factor s_j for the maximum conductance g_j , where $s_j = 1$ was the original literature value. The likelihood of observing the data \mathbf{Y} with K time points given the model parameters θ was

$$p(\mathbf{Y} | \theta) = \frac{1}{(2\pi\sigma^2)^{K/2}} \exp\left(-\frac{\sum_{i=1}^K (Y_i - y_i)^2}{2\sigma^2}\right). \quad (18)$$

The posterior distribution of the parameters was

$$p(\theta | \mathbf{Y}) = \frac{p(\mathbf{Y} | \theta)p(\theta)}{p(\mathbf{Y})} \quad (19)$$

$$p(\theta | \mathbf{Y}) \propto p(\mathbf{Y} | \theta)p(\theta), \quad (20)$$

where $p(\theta)$ is the prior, and $p(\mathbf{Y})$ is the marginal likelihood which is a constant. Uniform priors were used $\mathcal{U}(0.04, 25)$ for the scaling of the conductance values, which was wider than the subspace we used for computing the GSA to test its robustness for parameters outside the design parameter space.

The posterior distributions of the parameters were estimated using a Monte-Carlo based sampling scheme—a population MCMC [44] algorithm with adaptive Metropolis as the base sampler—via our open source Python package, PINTS [43]. We ran four chains for the population MCMC, each with 4×10^4 samples, and discarded the first 10^4 samples as warm-up period.

3. Results

In this section we briefly motivate our OED approach before presenting 12 new protocols derived for voltage-clamp and 6 new protocols for current-clamp experiments. Various ways to evaluate the 'quality' of these optimised protocols are explored and we discuss some of the properties that we would like or expect them to have. To check the designs, we evaluate them using both theoretical optimality measures and practical tests in which we infer parameters from simulated data. Finally, we compare the OED performance against designs found in the literature.

3.1. Optimal experimental designs for patch-clamp experiments

OED provides a framework for obtaining high-quality, statistically grounded designs \mathbf{u} that are optimal with respect to a statistical criterion Φ . It is based on the assumption that we can parameterise the designs \mathbf{u} with a *control or design variable vector* \mathbf{d} such that it can be optimised with the criterion Φ that depends on the choice of a model M . Two types of experimental protocols (\mathbf{u}) were optimised: voltage clamp and current clamp (see § 2.2). We defined voltage-clamp protocols as sequences of steps with a magnitude and duration that could be varied by OED as the design variables \mathbf{d} . Our current-clamp protocols consisted of short bursts of current injection with a fixed magnitude and duration, here the interval between burst was used as design variable (see Fig. 1). OED can also work within a variety of constraints, such as restrictions in duration of the experiment or applied voltage ranges, to ensure the optimal designs are practically feasible.

Experiment designs $\mathbf{u}(\mathbf{d})$ were optimised based on a design measure which consists of a choice of the optimal design criterion and a choice of model used to perform the design, using a global optimisation algorithm. For voltage-clamp experiments, we used six design criteria (LSA A-, D-, E*-designs, and GSA A-, D-, E*-designs) and two types of model, giving us in total 12 optimal design strategies (see § 2.3). These design criteria can be interpreted as properties (the shape and size) of the *confidence hyper-ellipsoid* for the calibrated model parameters θ [34,35]. The A-optimal design can be interpreted as minimising the average variance of the confidence ellipsoid. The D-optimal design minimises the volume of the confidence ellipsoid. The E*-optimal design minimises the ratio of the length of the largest to the smallest axis, making the ellipsoid as spherical as possible. The resulting optimised protocols using different strategies are shown in Fig. 2 (Protocols A–L), with the corresponding current ($\mathbf{y} = I_{\text{obs}}$) simulated using the O'Hara et al. [20] model (the corresponding eigenvalue spectra are shown in Supplementary Figures). For current-clamp experiments, we used three design criteria (the LSA A-, D-, E*-designs) and two types of model, giving us in total 6 optimal design strategies. The resulting optimised protocols using different strategies are shown in Fig. 3 (Protocols O–T) with the corresponding membrane voltage ($\mathbf{y} = V_m$) simulated using the O'Hara et al. [20] model.

Each of the protocols appears to elicit rich and varied dynamics. For voltage-clamp protocols, these optimal protocols are also shorter in duration than most of the conventional protocols, such as Protocol M, where long holding steps are usually required for bringing the cells back to quasi-steady state. Since these optimal protocols were designed to maximise the information for all model

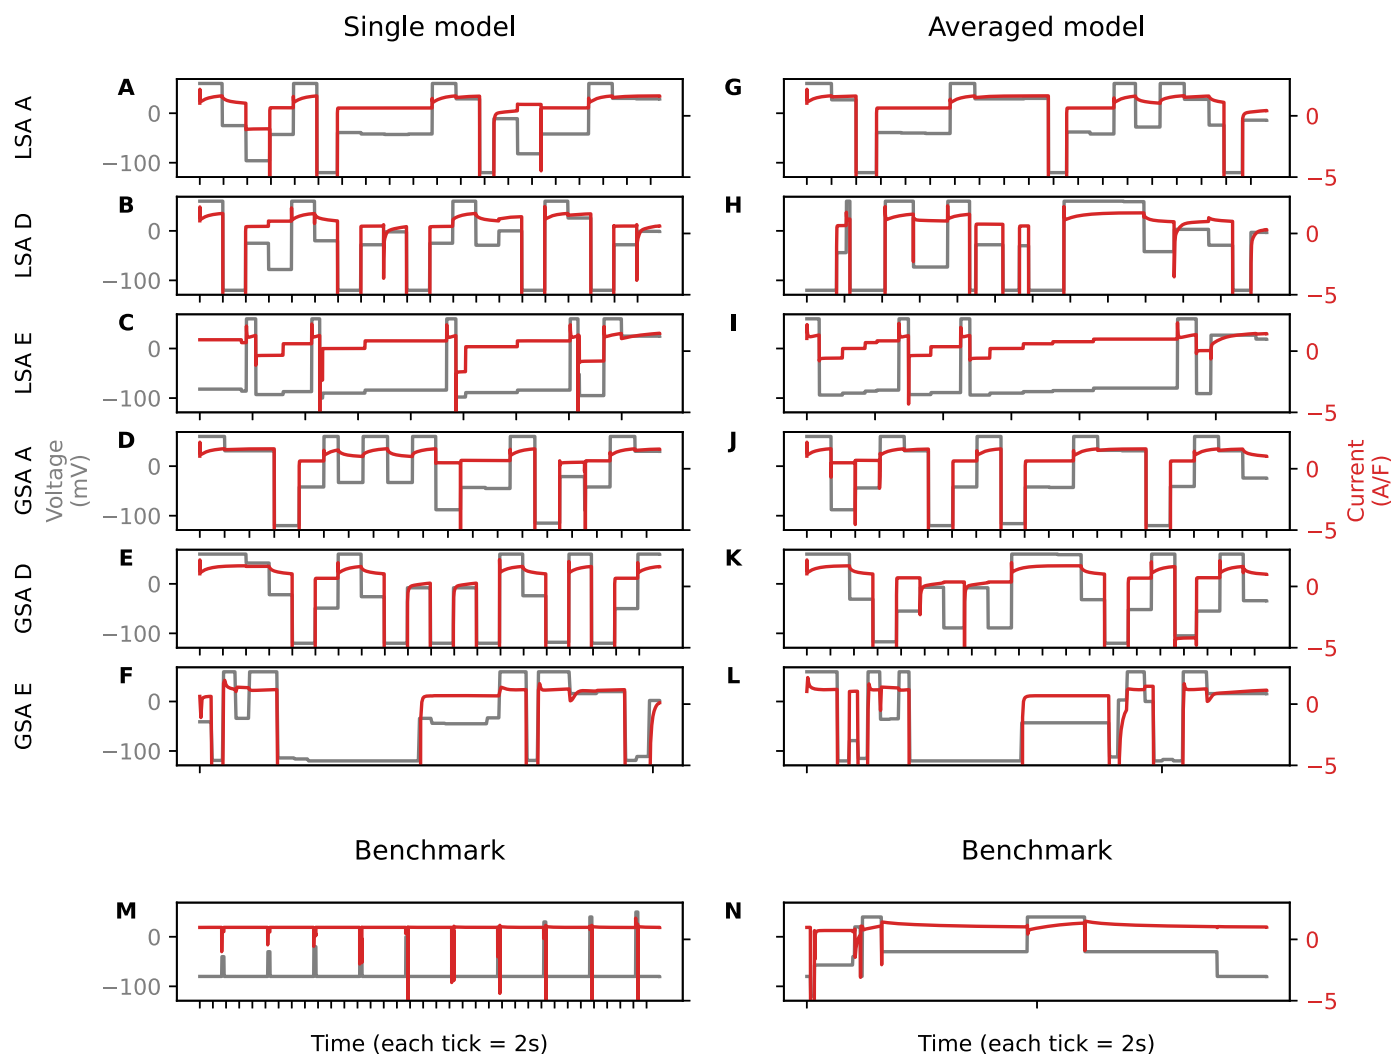

Fig. 2. (A–L) The optimised protocols (shown in grey, values on left axis) using different criteria and the corresponding I_{obs} (shown in red, values on right axis) simulated using the O’Hara et al. [20] model. Rows are protocols optimised with different optimal design criteria: the LSA A-, D-, E*-designs, and the GSA A-, D-, E*-designs. Columns are protocols optimised based on different types of models: the single model criterion, and the averaged model criterion. (M, N) The benchmark protocols from Lei et al. [45] and from Groenendaal et al. [30]. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

parameters for inference, we evaluate the performance of these optimised protocols and compare them against some protocols from the literature.

3.2. Do OEDs help us find model parameters?

Taking a practical approach, we generated synthetic (simulated) data under these optimised protocols $\mathbf{u}(\hat{\mathbf{d}})$, then asked the following questions: (i) can we identify the model parameters θ correctly using these synthetic data? (ii) how does the error, if any, and uncertainty in the parameters vary between these optimised protocols?

We generated synthetic data using the O’Hara et al. [20] model with i.i.d. Gaussian synthetic noise $\mathcal{N}(0, \sigma^2)$ with zero mean and standard deviation $\sigma = 0.15 \text{ AF}^{-1}$ for voltage clamp and $\sigma = 1 \text{ mV}$ for current clamp. Then the same model was used to fit the synthetic data, to test whether we can identify the maximum conductance parameters θ when we have a good estimate of the kinetics. Posterior distributions of the parameters were estimated using a Markov chain Monte Carlo (MCMC) based sampling scheme [44], where the final chains converged with $\hat{R} < 1.1$ for all parameters [46].

In terms of reducing the uncertainty and error in the inferred parameters, the two most successful optimal designs $\hat{\mathbf{d}}$ for voltage-clamp experiments were the LSA D-design and GSA A-design for the O’Hara et al. [20] model (Protocols B and D), as shown in Fig. 4A. Each chain returned a posterior distribution over the parameters, since all chains converge and they are all very similar to each other, we use all three chains to compute the marginal parameter distributions (per parameter). The mean (over all the parameters) root-mean-square error (RMSE) of these distributions to the true values is shown in Fig. 4B for all of the voltage-clamp protocols. The posterior RMSEs of the individual parameter scaling factors are shown in Supplementary Table S1, which shows that the dominant contribution to the error was from s_{NaCa} . We expect this is because I_{NaCa} is reasonably small and has fairly linear dynamics under voltage clamp which happens to allow it to compensate for the sum of the errors in the other inferred conductances.

For current-clamp experiments, all the OED results had a similar posterior width, with the most successful optimal design to be the LSA A-design for the single model (Protocol O) as shown in Fig. 5A. The mean (over all the parameters) RMSE of these distributions is shown in Fig. 5B for all of the current-clamp protocols, and the individual parameters are shown in Supplementary

Fig. 3. The optimised protocols (shown in grey, the positions at which stimuli were applied) using different criteria and the corresponding membrane voltage V_m (shown in red, values on right axis) simulated using the O'Hara et al. [20] model. Rows are protocols optimised with different optimal design criteria: the LSA A-, D-, E'-designs. Protocols were optimised based on (O–Q) the single model criterion, and (R–T) the averaged model criterion. (U/V) The benchmark protocols with 1Hz pacing, where Protocol U uses only the AP biomarkers for parameter inference, and Protocol V uses the full time series. (W) Another benchmark protocol from Groenendaal et al. [30]. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Table S2. The same analyses were also repeated for the ten Tusscher et al. [23] model, shown in Supplementary Figures S3 & S4, and Supplementary Tables S3 & S4. Similar results as for the O'Hara et al. [20] model were observed, demonstrating the conclusions may hold across further models, especially those with similar dynamics.

3.3. Cross-measure assessments of OEDs

We may also expect the best protocol from those OEDs would be a robust good 'all-round' protocol. Each of the OED is by definition optimal under a given design measure, whilst a robust good all-round design would not be the worst under another design measure and, on average, should be good under all measures.

The performance of all the optimised protocols under a particular experimental mode were compared across all the design measures; a design measure is defined by the choices of the model and the design criterion. We used the ten Tusscher et al. [23] model, the Fink et al. [24] model, the O'Hara et al. [20] model, the Dutta et al. [47] model, the Tomek et al. [26] model, and the averaged model to assess the OED performance; the O'Hara et al. [20] model

and the averaged model were used to optimise the protocols, and the remaining four were included to assess how these optimised protocols perform should data really arise from cells that are better described by these other models. We used the same criteria to assess the OEDs, and their combinations form what we refer to as the cross-measure matrix. Each design measure entry of the cross-measure matrix was normalised to 0-100% with the best and the worst values seen across all the OED protocols such that it can be compared with other design measures.

Examples of cross-measure assessments for the OEDs are shown in Fig. 6A for voltage clamp and Fig. 7A for current clamp. Fig. 6A shows our best voltage-clamp protocol design, the OED with the 'averaged model score' under GSA D-criterion (Protocol K), which performs well under all measures and model currents. Fig. 7A shows our best current-clamp protocol design, the OED with the 'averaged model score' under LSA A-criterion (Protocol R), which performs well under all measures and model currents. The 'best' protocols in this assessment were decided based simply on the mean of all entries in the cross-measure matrix. The averaged score for each optimised protocol is shown in Fig. 6C for voltage clamp and Fig. 7C for current clamp.

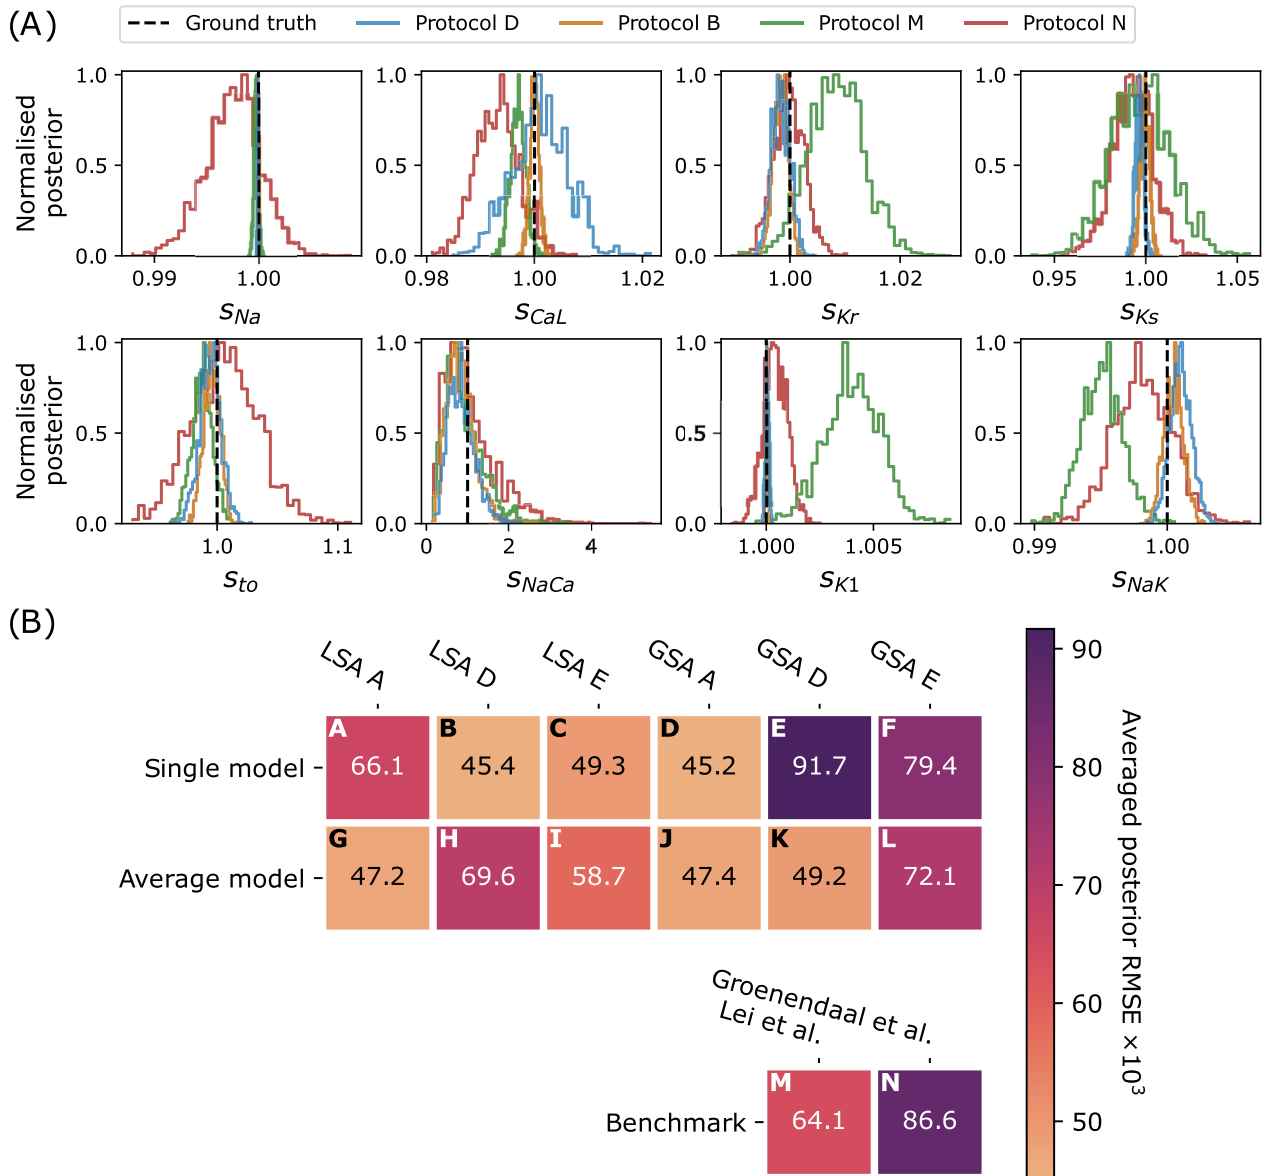

Fig. 4. The posterior distribution of the parameters for the synthetic study with voltage clamp, generated with the O'Hara et al. [20] model and fitted with the same model. **(A)** The marginal posterior for the best two protocols: LSA D- and GSA A-designs for the O'Hara et al. [20] model (Protocols B and D), according to the mean RMSE of the marginal posterior to the true values, and for the two benchmark protocols. **(B)** The mean RMSE of the marginal posterior for all of the optimised protocols, as well as the benchmark protocols.

Fig. 6 C and Fig. 7 C show that the protocols based on multiple models (bottom row) are similar to those based on only the O'Hara et al. [20] model (top row), although the best protocols for each experimental mode is based on multiple models. This may be expected as the protocols based on only one model may perform relatively badly under other models. We also noticed that the protocols based on the LSA E criterion are worse than the other LSA criteria. Finally, in Fig. 6C, the protocols based on the GSA criteria are better than (or similar to) their LSA counterparts, apart from the E*-design using the O'Hara et al. [20] model.

3.4. OEDs outperform literature experimental designs

Finally, we assessed the OED results by comparing their performance against some of the designs of experiments in the

literature—a benchmark comparison. For voltage-clamp experiments, we used (1) Protocol M: a simple step protocol from Lei et al. [45] and (2) Protocol N: an expertly-designed protocol from Groenendaal et al. [30] to benchmark the performance. For current-clamp experiments, we used (1) Protocol W: the random pacing protocol from Groenendaal et al. [30]; (2) Protocol V: a simple 1Hz constant pacing protocol; and (3) Protocol U: the derived summary statistics (biomarkers) based on 1Hz pacing, which are commonly used in the literature [48–55].

For the voltage-clamp protocols, the benchmark protocol from Lei et al. [45] (Protocol M) shown in Fig. 6B performed badly for most of the design measures, which may be expected as it is not designed using any of these measures. Similarly, the protocol from Groenendaal et al. [30] scored badly compared to OED protocols, although its score was, on average, just twice that of the worst

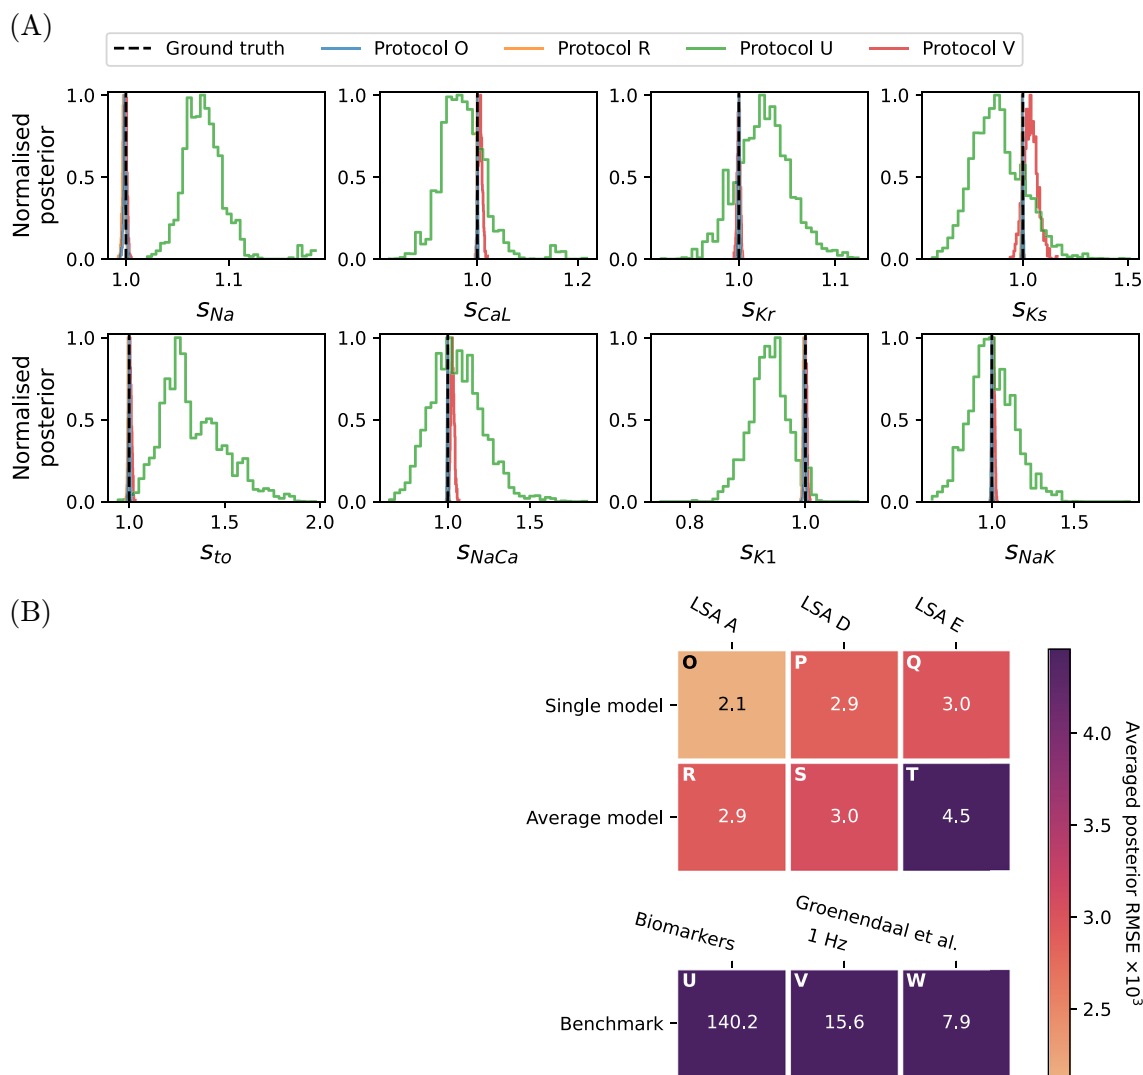

Fig. 5. The posterior distribution of the parameters for the synthetic study with current clamp, generated with the O'Hara et al. [20] model and fitted with the same model. (A) The marginal posterior for the best two protocols: LSA A-design (Protocols O and R), according to the mean RMSE of the marginal posterior to the true values, and for the two benchmark protocols. Note that y-axes are rescaled to unity for visualisation purpose. Magnification of this figure around true value is provided in Supplementary Figures. (B) The mean RMSE of the marginal posterior for all of the optimised protocols, as well as the benchmark protocols.

OED protocol (Protocol F) which is impressive given its manual design. Fig. 4 also shows that the benchmark protocols resulted in considerably wider posterior distributions than most of the optimised protocols. Additionally, Supplementary Table S1 shows that Protocol B improves the posterior RMSEs for all of the parameters compared to the benchmark protocols; in Fig. 4B, where Protocol E appeared to be the worst, it actually helped identify all the other parameters better than the benchmark protocols apart from S_{NaCa} . Often the number of data samples (or data points) in the i.i.d. Gaussian likelihood that we use is a major factor determining the width of the posterior. Here even for the protocol from Lei et al. [45] (Protocol M) which is much longer in duration (hence more data samples) than any of the optimised protocols, the width of its posterior is still bigger than most of the optimised protocols. Interestingly, even though the protocol by Groenendaal et al. [30] (Protocol N) was designed specifically to tease out different dynamics of the ionic currents, the width of the posterior is similar to that of the protocol from Lei et al. [45]. Overall, this shows that the OED methods were successful in reducing the parameter uncertainty for voltage-clamp experiments.

For current-clamp experiments, the biomarkers that we used were action potential duration (APD) at 10% repolarisation (APD_{10}), APD_{20} , APD_{30} , APD_{40} , APD_{50} , APD_{60} , APD_{70} , APD_{80} , APD_{90} , triangularisation (defined as $APD_{90} - APD_{40}$), plateau duration, area under the curve of voltage trace (at APD_{30}), maximum upstroke rate/velocity (MUR), resting potential, maximum voltage (V_{max}), dome peak, and action potential amplitude (APA) which were used in Bartolucci et al. [48], Britton et al. [49], Jæger et al. [50–52], Paci et al. [53,54], Tveito et al. [55]. To perform practical evaluations for biomarkers, we used a percentage difference for calculating the likelihood as it was done similarly in e.g. Jæger et al. [50], Tveito et al. [55]. We first note that the same was observed for the 1Hz pacing protocol (Protocol V) and the Groenendaal et al. [30] protocol (Protocol W): not only is the cross evaluation matrix consistently worse than the OED protocols (Fig. 7B), but the posterior obtained in the practical assessment is also wider than all of the OED protocols (Fig. 5). The results from using the biomarkers (Protocol U, Fig. 5A) were not only more uncertain than the other approaches but also biased in some of the parameter estimates, e.g. I_{Na} and I_{to} . Since Protocol W was designed to improve the in-

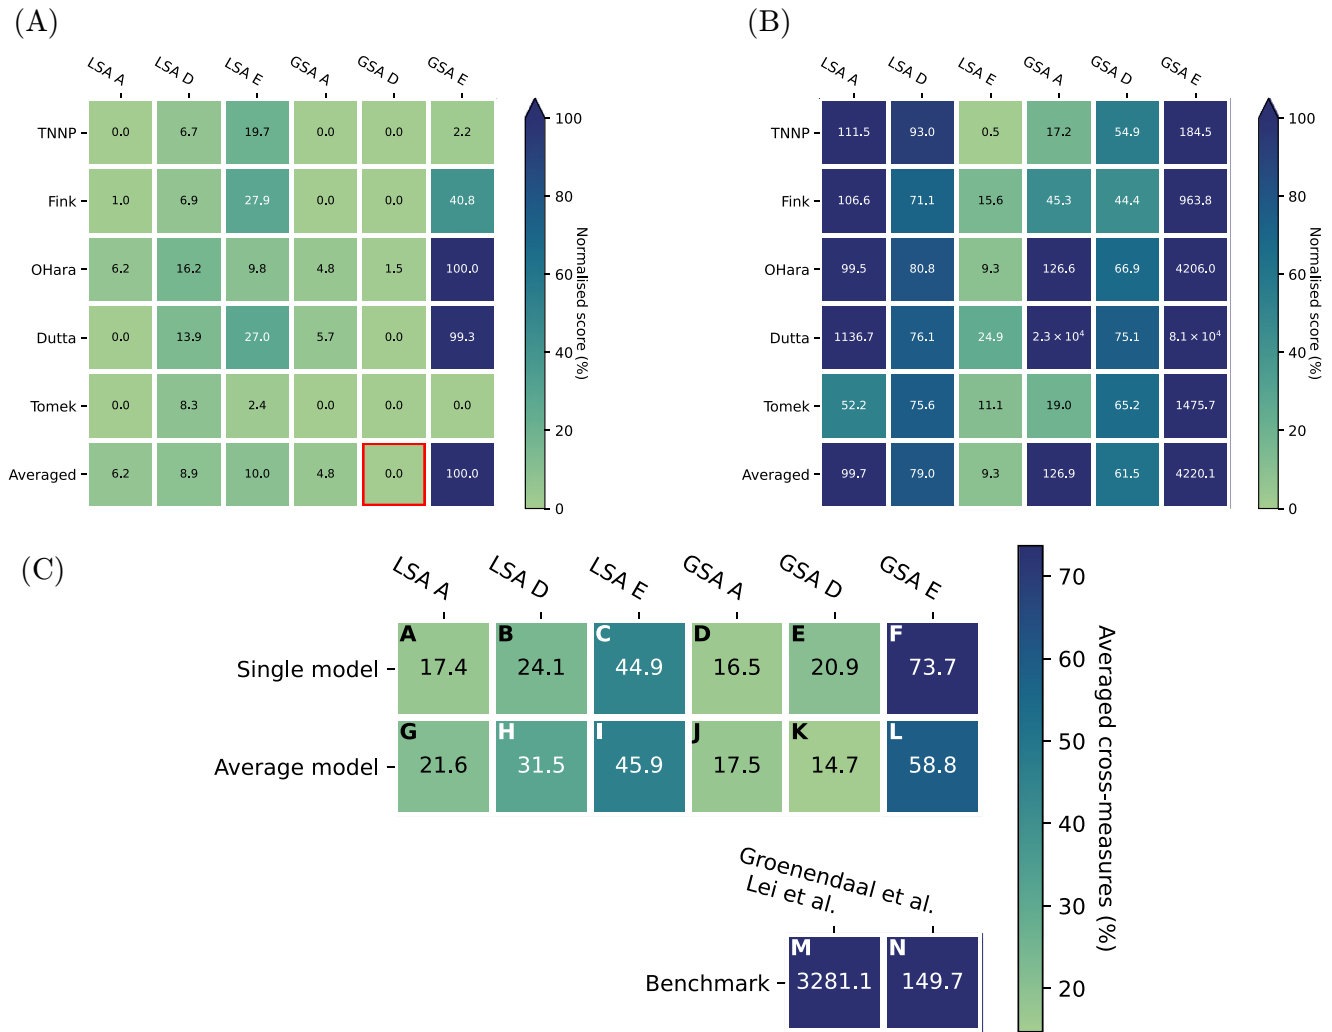

Fig. 6. Cross-measure evaluations for the optimised voltage-clamp protocols, compared against the benchmark protocols. **(A)** The normalised cross-measure matrix for the best protocol, Protocol K, optimised using the GSA D-criterion and the averaged model (indicated with the red box). **(B)** The matrix for the worst protocol, Protocol M, from Lei et al. [45]. **(C)** The mean of the normalised cross-measure evaluations for all of the optimised protocols, as well as the benchmark protocols. formation gain by randomly pacing the system, it outperformed Protocols U and V. However, we showed that the OED protocols which maximised the information gain were better in estimating the model parameters than those in the literature, including Protocol W.

4. Discussion

We have applied OED to various AP models to design voltage-clamp and current-clamp protocols for fitting maximum conductances. This is, to our knowledge, the first time such an approach has been taken in cardiac cellular electrophysiology. Some studies have looked into designing experiments for model calibration from *expertly* designed protocols, ranging from calibrating models of individual ionic current dynamics [27–29,56,57] to whole-cell models of APs of cardiomyocytes [30]; similarly in neuroscience [58,59] too. However, these protocols are not truly ‘optimal’ under a certain statistical or objective measure; they are designed through (subjective) expert views. Our (objectively) optimised protocols successfully reduced the uncertainty in the inferred parameters, compared to some of the conventional protocols.

We explored various designs adapted from the OED literature [12,16,18], with the aim of designing experiments that help parameter reconstruction to be more accurate and reliable. Most of them were able to improve the uncertainty in the inferred parameters compared to the benchmark protocols, as assessed via our practical evaluations. We tried to seek the best protocol amongst the OED generated protocols. However, we were not able to identify the best one, as each of them perform slightly differently under different situations, although the E*-design appeared to balance the minimum and maximum eigenvalues of FIM by reducing the highest sensitivity which made the resulting protocols relatively short and resulted in one of the worst performances. For example Protocol K was the best in the cross-measures comparison, whilst Protocol D was better in reducing parameter uncertainty and error. We found that the protocols based on averaged model were consistently (slightly) better than the others, which may be a better way for designing patch-clamp protocols, which implicitly makes some allowance for differences in ion current kinetics. Although one could easily extend the presented methodology to create optimal protocols for more parameters, the OED approach does not automatically solve all potential issues, e.g. an a-priori unidentifiability problem, or computational challenges such as the curse of dimensionality in large-scale parameter inference.

Fitting conductances to whole-cell recordings while using ion channel kinetics models taken (or slightly adapted) from the literature, has been commonly used [8]. Many inference approaches and biomarkers have been adopted, including multivariate regression [60], history matching [61], “population of models” [62], and moment-matching [63], and all of them assumed “out of the box” or only slightly modified kinetics models when fitting maximum conductances. Similarly Johnstone et al. [64] adapted a Bayesian approach with MCMC to infer maximum conductances using AP recordings. Groenendaal et al. [30] proposed to use (cell-specific) voltage-clamp and current-clamp data with a genetic algorithm to find maximum conductances in an AP model. Some of these methods were included in our benchmark comparison for our approach; we have shown that optimal designs outperform these literature methods in terms of recovering parameters from simulated data.

When inspecting the error (and uncertainty) of the inferred parameters from voltage- and current-clamp experiments (Figs. 4 & 5), current clamping appears to be the superior methodology for parameter reconstruction for most of the protocols (but not simply with biomarker-equivalent summary statistics as discussed below). This could be due to the highly nonlinear interaction between all of the currents in current clamping, whilst voltage clamping by

definition unties these and turns the system into independent current components. These nonlinear interactions in current-clamp mode may actually help pin down the parameters, because even though some of the currents are small in some parts of the data traces, we may gain information about these currents by the help of the nonlinear interactions with the remaining currents. However, this phenomenon is based on the assumption that there are no model discrepancies. In practice we believe voltage clamping may provide important information by studying each current more ‘independently’, i.e. less vulnerable to discrepancy in one current affecting inferences about another, therefore we would not advocate to do just one type of experiment but not the other.

Amongst all the methods that we compared, the biomarker approach performed the worst, even though it has been one of the most popular approaches. We further note that some of the biases in the biomarker posteriors were due to the biases introduced in estimating the biomarkers with noisy data. Such an issue is illustrated in Fig. 8A which is a *consequence* of using biomarker estimations from noisy AP traces. In Fig. 8A, the biomarkers were estimated for 1000 noise realisations and compared against the biomarkers taken from idealised noise-free data (dashed line). For example, there are no simple ways of estimating the unbiased (i.e. neither over- nor under-estimating) maximum voltage or the AP amplitude with noisy AP traces; if we simply define the maximum voltage as the maximum voltage value of the noisy data, as done here, then we will overestimate the actual maximum voltage most of the time. This is because we have a number of data samples (sampling time points) around the underlying maximum voltage where the noise is centred, then the noisy data will have values bigger (as well as smaller) than the mean most of the time, giving an overestimated maximum voltage value. However, if we define the maximum voltage as the averaged value over a (short) period of time around the maximum voltage value of the noisy data, then the maximum voltage will be biased differently depending on the duration of the averaging period and the shape of the AP. Therefore, depending on the data postprocessing procedure, the biomarkers, and hence model parameters inferred from these, can be biased differently.

The biases introduced during biomarker extraction (Fig. 8A) therefore affect posterior predictions. Fig. 8B shows such posterior predictions using the parameter posteriors shown in Fig. 5, where grey and black (dashed) lines show the data and the underlying ground truth, blue and orange show the predictions from the posteriors estimated using Protocol U (biomarkers) and Protocol O (LSA A with single model). The inset of Fig. 8B shows a magnification around the apex of the AP, highlighting the biases of the posterior predictions with biomarkers (blue) as compared to the OED results (orange). These biases may in turn cause issues during model predictions for unseen situations. We illustrate these issues in Fig. 8C which attempts to predict the AP under a 90% reduction of I_{Kr} together with a 50% reduction of I_{Ks} . The huge variability and inaccuracy of the posterior prediction using biomarkers (blue) are consequences of both increased *parameter unidentifiability* as well as bias discussed above, as shown by comparison with the predictions with parameters inferred by fitting to the full time traces from Protocol O (orange).

Several limitations of this work suggest future studies to advance the design of experimental protocols. First, all existing OED approaches, to our knowledge, provide optimal designs only under the assumption of having a correct underlying model, meaning when there is discrepancy between the model we use and the real system (including the remaining parameters of the model that were left out for the design and inference, experimental artefacts [65–68] and noise/observation model error [69–72]) then there is no guarantee that the designs will work better, or even work well, as discussed in Lei et al. [73], Lei [74]. We believe the presented

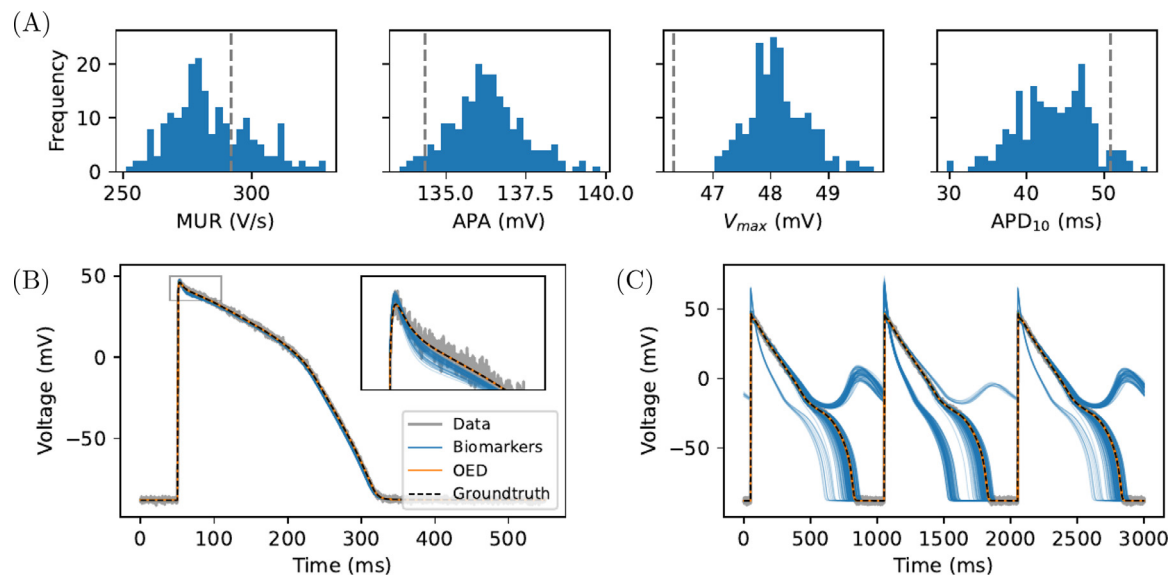

Fig. 8. Undesired effects of using biomarkers (Protocol U) for AP parameter inference. **(A)** Various biomarkers were estimated for 1000 noise realisations and compared against the biomarkers estimated without noise (dashed line). **(B)** Posterior predictions using the parameter posterior samples shown in Fig. 5 (blue for Protocol U, biomarkers, and orange for Protocol O, OED) for 1Hz prepaced AP. **(C)** Posterior predictions for 1Hz prepaced AP under a 90% reduction of I_{Kr} together with a 50% reduction of I_{Ks} . (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

approach is the first step towards promoting and setting up optimisation of experimental designs in the field. In the future, incorporating the minimisation of the impact of additional uncertainties in the underlying mathematical descriptions as part of the OED measures will be an important next step towards improved future rounds of experimental design. The results, however, have generated experimental protocols that can readily be tested experimentally, especially since these designs can be implemented in most cellular electrophysiology laboratories, and these multiple automatically generated protocols could also potentially be used to quantify predictive uncertainty due to model discrepancy [75]. A second limitation is that although we tested 18 OEDs, most of these are 'classical' design criteria that relies on certain approximation of the covariance of the estimates. In future work, we intend to determine whether more complex criteria or approaches, such as Bayesian decision theoretic approach [76,77] and reinforcement approaches [78], can improve the protocol design.

In summary, we have demonstrated that using mechanistic mathematical modelling and optimal experimental design can improve identification of model parameters and hence its theoretical predictive power. This work offers a methodology to automatically, objectively develop experimental protocols that can alleviate the issue of model parameter unidentifiability when collecting new experimental data.
